Abstract

Inter-organizational business processes involve multiple independent organizations collaborating to achieve mutual interests. Process mining techniques have the potential to allow these organizations to enhance operational efficiency, improve performance, and deepen the understanding of their business based on the recorded process event data. However, inter-organizational process mining faces substantial challenges, including topical secrecy concerns: The involved organizations may not be willing to expose their own data to run mining algorithms jointly with their counterparts or third parties. In this paper, we introduce CONFINE, a novel approach that unlocks process mining on multiple actors' process event data while safeguarding the secrecy and integrity of the original records in an inter-organizational business setting. To ensure that the phases of the presented interaction protocol are secure and that the processed information is hidden from involved and external actors alike, our approach resorts to a decentralized architecture comprised of trusted applications running in Trusted Execution Environments (TEEs). We show the feasibility of our solution by showcasing its application to a healthcare scenario and evaluating our implementation in terms of memory usage and scalability on real-world event logs.

Keywords: Collaborative information

1. Introduction

In today's business landscape, organizations constantly seek ways to enhance operational efficiency, increase performance, and gain valuable insights to improve their processes. Process mining offers techniques to discover, monitor, and improve business processes by extracting knowledge from chronological records known as event logs [1]. Process-aware information systems record events referring to activities and interactions within a business process. The vast majority of process mining contributions consider intra-organizational settings, in which business processes are executed inside individual organizations. However, organizations increasingly recognize the value of collaboration and synergy in achieving operational excellence. Inter-organizational business processes involve several independent organizations cooperating to achieve a shared objective [2]. Despite the advantages of transparency, performance optimization, and benchmarking that companies can gain, inter-organizational process mining raises challenges that hinder its application. The major issue concerns confidentiality. Companies are reluctant to share private information required to execute process mining algorithms with their partners [3]. Indeed, letting sensitive operational data traverse organizational boundaries introduces concerns about data privacy, security, and compliance with internal regulations [4]. Trusted Execution Environments (TEEs) [5] can serve as fundamental enablers to balance the need for insights with the need to protect sensitive information in inter-organizational settings. TEEs offer secure contexts that guarantee code integrity and data confidentiality before, during, and after its utilization.

In this paper, we propose CONFINE, a novel approach and tool aimed at enhanc-

ing collaborative information system architectures with secrecy-preserving process mining capabilities in a decentralized fashion. It resorts to *trusted applications* running in TEEs to preserve the secrecy and integrity of shared data. To pursue this aim, we design a decentralized architecture for a four-staged protocol: (i) The initial exchange of preliminary metadata, (ii) the attestation of the miner entity, (iii) the secure transmission and privacy-preserving merge of encrypted information segments amid multiple parties, (iv) the isolated and verifiable computation of process discovery algorithms on joined data. We evaluate our proof-of-concept implementation against synthetic and real-world-based data with a convergence test followed by experiments to assess the scalability of our approach.

The remainder of this paper is as follows. Sect. 2 provides an overview of related work. In Sect. 3, we introduce a motivating use-case scenario in healthcare. We present the CONFINE approach in Sect. 5. We describe the implementation of our approach in Sect. 6. In Sect. 7, we report on the efficacy and efficiency tests for our solution. Finally, we conclude our work and outline future research directions in Sect. 8.

39 2. Background and Related Work

40 2.1. Background

41 2.2. Related Work

Despite the relative recency of this research branch across process mining and collaborative information systems, scientific literature already includes noticeable contributions to inter-organizational process mining. The work of Müller et al. [6] focuses on data privacy and security within third-party systems that mine data generated from external providers on demand. To safeguard the integrity of data earmarked for mining purposes, their research introduces a conceptual architecture that entails

the execution of process mining algorithms within a cloud service environment, fortified with Trusted Execution Environments. Drawing inspiration from this foundational contribution, our research work seeks to design a decentralized approach characterized by organizational autonomy in the execution of process mining algorithms, devoid of synchronization mechanisms involvement taking place between the involved parties. A notable departure from the framework of Müller et al. lies in the fact that here each participating organization retains the discretion to choose when and how mining operations are conducted. Moreover, we bypass the idea of fixed roles, engineering a peer-to-peer scenario in which organizations can simultaneously be data provisioners or miners. Elkoumy et al. [7, 8] present Shareprom. Like our work, their solution offers a means for independent entities to execute process mining algorithms in inter-organizational settings while safeguarding their proprietary input data from exposure to external parties operating within the same context. Shareprom's functionality, though, is confined to the execution of operations involving event log abstractions [9] represented as directed acyclic graphs, which the parties employ as intermediate pre-elaboration to be fed into secure multiparty computation (SMPC) [10]. As the authors remark, relying on this specific graph representation imposes constraints that may prove limiting in various process mining scenarios. In contrast, our approach allows for the secure, ciphered transmission of event logs to process mining nodes as a whole. Moreover, SMPC-based solutions require computationally intensive operations and synchronous cooperation among multiple parties, which make these protocols challenging to manage as the number of participants scales up [11]. In our research work, individual computing nodes run the calculations, thus not requiring synchronization with other machines once the input data is loaded. We are confronted with the imperative task of integrating event logs originat-

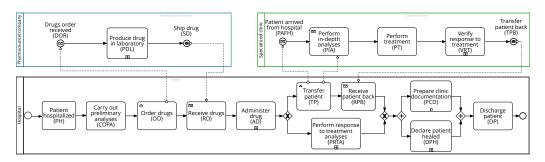

Figure 1: A BPMN collaboration diagram of a simplified healthcare scenario

ing from different data sources and reconstructing consistent traces that describe collaborative process executions. Consequently, we engage in an examination of methodologies delineated within the literature, each of which offers insights into the merging of event logs within inter-organizational settings. The work of Claes et al. [12] holds particular significance for our research efforts. Their seminal study introduces a two-step mechanism operating at the structured data level, contingent upon the configuration and subsequent application of merging rules. Each such rule indicates the relations between attributes of the traces and/or the activities that must hold across distinct traces to be combined. In accordance with their principles, our research incorporates a structured data-level merge based on case references and timestamps as merging attributes. The research by Hernandez et al. [13] posits a methodology functioning at the raw data level. Their approach represents traces and activities as bag-of-words vectors, subject to cosine similarity measurements 85 to discern links and relationships between the traces earmarked for combination. An appealing aspect of this approach lies in its capacity to generalize the challenge of merging without necessitating a-priori knowledge of the underlying semantics inherent to the logs under consideration. However, it entails computational overhead in the treatment of data that can interfere with the overall effectiveness of our approach.

Table 1: Events from cases 312 (Alice) and 711 (Bob) recorded by the hospital, the specialized clinic, and the pharmaceutical company

	Hospital							Pł

1 3. Motivating Scenario

For our motivating scenario, we focus on a simplified hospitalization process for 92 the treatment of rare diseases. The process model is depicted as a BPMN diagram in Fig. 1 and involves the cooperation of three parties: a hospital, a pharmaceutical company, and a specialized clinic. For the sake of simplicity, we describe the process through two cases, recorded by the information systems as in Table 2. Alice's journey (case 312) begins when she enters the hospital for the preliminary examinations 97 (patient hospitalized, PH). The hospital then places an order for the drugs (OD) to the pharmaceutical company for treating Alice's specific condition. Afterwards, the pharmaceutical company acknowledges that the drugs order is received (DOR), proceeds to produce the drugs in the laboratory (PDL), and ships the drugs (SD) back 101 to the hospital. Upon receiving the medications, the hospital administers the drug 102 (AD), and conducts an assessment to determine if Alice can be treated internally. If 103 specialized care is required, the hospital transfers the patient (TP) to the specialized clinic. When the patient arrives from the hospital (PAFH), the specialized clinic 105 performs in-depth analyses (PIA) and proceeds with the treatment (PT). Once the 106 specialized clinic had completed the evaluations and verified the response to the 107 treatment (VRT), it transfers the patient back (TPB). The hospital receives the patient

back (RPB) and prepares the clinical documentation (PCD). If Alice has successfully recovered, the hospital declares the patient as healed (DPH). When Alice's treatment is complete, the hospital discharges the patient (DP). Bob (case 711) enters the hospital a few hours later than Alice. His hospitalization process is similar to Alice's. However, he does not need specialized care, and his case is only treated by the hospital. Therefore, the hospital performs the response to treatment analyses (PRTA) instead of transferring him to the specialized clinic.

Both the National Institute of Statistics of the country in which the three organiza-116 tions reside and the University that hosts the hospital wish to uncover information on this inter-organizational process for reporting and auditing purposes [14] via process 118 analytics. The involved organizations share the urge for such an analysis and wish to 119 be able to repeat the mining task also in-house. The hospital, the specialized clinic, 120 and the pharmaceutical company have a partial view of the overall unfolding of the inter-organizational process as they record the events stemming from the parts of their pertinence. In Table 1, we show the cases 312 and 711 and the corresponding 123 traces recorded by the hospital (i.e., T_{312}^H and T_{711}^H), the specialized clinic (i.e., T_{312}^S and ${\cal T}_{711}^S$), and the pharmaceutical company (i.e., ${\cal T}_{312}^C$ and ${\cal T}_{711}^C$). Those traces are projections of the two combined ones for the whole inter-organizational process: $T_{312} = \langle \mathsf{PH}, \mathsf{COPA}, \mathsf{OD}, \mathsf{DOR}, \mathsf{PDL}, \mathsf{SD}, \mathsf{RD}, \mathsf{AD}, \mathsf{TP}, \mathsf{PAFH}, \mathsf{PIA}, \mathsf{PT}, \mathsf{VRT}, \mathsf{TPB},$ RPB, DPH, PCD, DP \rangle and $T_{711} = \langle PH, COPA, OD, DOR, PDL, SD, RD, AD, TP,$ DPH, PCD, DP\. Results stemming from the analysis of the local cases would not provide a full picture. Data should be merged. However, to preserve the privacy of the people involved and safeguard the confidentiality of the information, the involved parties cannot give open access to their traces to other organizations. The diverging interests (being able to conduct process mining on data from multiple sources without

giving away the local event logs in-clear) motivate our research. In the following, we describe the design of our solution.

6 4. Notation

Given a finite set of events \hat{E} and a total-order relation \leq subset of $\hat{E} \times \hat{E}$, we 137 identify an event log as the totally ordered set (\hat{E}, \leq) . In the example, ... Let $\widehat{\text{CID}}$ be Add exama finite non-empty set of symbols such that $|\widehat{\text{CID}}| \leq |\widehat{\text{E}}|$. We assume that every event be 139 associated with a case identifier $cid \in \widehat{CID}$ via a total surjective function $\mathfrak{id} : \widehat{E} \to \widehat{CID}$ such that the restriction $<_{cid} = \le \cap \{e \in \widehat{E} : i\mathfrak{d}(e) = cid\}^2$ of total order \le on all events mapped to the same *cid* is strict (i.e., if $e \le e'$ with $e \ne e'$ and $\mathfrak{id}(e) = \mathfrak{id}(e')$ then $e' \le e$). In the example, . . . In other words, id acts as an equivalence relation partitioning \hat{E} into Add exam- $\left\{\hat{\mathbf{E}}_{cid}\right\}_{cid\in\widehat{\mathrm{CID}}}\subseteq 2^{\hat{\mathbf{E}}}$ based on the cid to which the events $e\in\hat{\mathbf{E}}_{cid}$ map, and imposing that events are linearly ordered by the restriction of \leq on every \hat{E}_{cid} . Every pair $(\hat{E}_{cid}, \prec_{cid})$ thus represents a finite linearly totally ordered set (or *loset* for brevity) with $\hat{E}_{cid} \subseteq \hat{E}$ and $<_{cid} \subseteq \widehat{E}_{cid} \times \widehat{E}_{cid} \subseteq \subseteq \subseteq \widehat{E} \times \widehat{E}$. Let $(\widehat{E}, <)$ be a loset and $(\widehat{E}', <')$, $(\widehat{E}'', <'')$ two (sub-) losets such that $\hat{E}' \cup \hat{E}'' \subseteq \hat{E}$ and $\hat{E}' \cap \hat{E}'' = \emptyset$, with \prec' and \prec'' being the restrictions of < on \hat{E}' and \hat{E}'' , respectively. We define the order-preserving union $\bigoplus: \hat{E}^3 \times \hat{E}^3 \to \hat{E}^3$ of losets as follows: $(\hat{E}', <') \bigoplus (\hat{E}'', <'') = (\hat{E}' \cup \hat{E}'', < \cap (\hat{E}' \cup \hat{E}'')^2)$. We can thus Continue here rederive the notion of case C_{cid} given a $cid \in \widehat{CID}$ as a loset of events mapping to vising the the same cid and ordered by the linear restriction < of \le over the events in C_{cid} : definition of order $cid = (\widehat{\mathbf{E}}_{cid}, \prec)$ where $C_{cid} = \langle e_1, ..., e_{|C_{cid}|} \rangle$ where $\mathfrak{id}(e_i) = cid \in \widehat{\mathrm{CID}}$ for every i s.t. preserving $1 \le i \le |C_{cid}|$ and $e_i < e_j$ for every $i \le j \le |C_{cid}|$. Notice that the cardinality of \hat{C} and union $\widehat{\text{CID}}$ coincide. Events are also the domain of a function $\mathfrak{p}: \widehat{\mathbb{E}} \to \widehat{\mathcal{P}}$ mapping events to

¹We employ the angular-bracket notation here for the sake of simplicity, although it is typically used for sequences. Unlike sequences, cases do not allow for the same event to occur more than once.

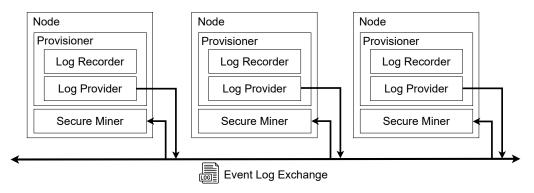

Figure 2: The CONFINE high-level architecture

log provisioners. In the example, . . . We shall denote with $C_{cid}^{\mathcal{P}}$ the loset consisting of every event $e \in C_{cid}$ such that $\mathfrak{p}(e) = \mathcal{P}$, with the restriction of the strict total order of C_{cid} on those events. In the example, . . . Gotta move this one earlier when we introduce the example with the partitioned event log. (Section 4.2??). Clarify the difference between segmentation (given a segsize, i.e., a segment of a case-part in a sublog) and partitioning (of a log into case-parts of sublogs. Then, prove that the pipeline of partitioning and segmentation has its inverse in the union and merge for soundness.

5. Design

- In this section, we present the high-level architecture of the CONFINE framework.
- We consider the main functionalities of each component, avoiding details on the
- employed technologies discussed in the next sections.

The CONFINE architecture at large. Our ar-

- 165 chitecture involves different information systems
- running on multiple machines. An organiza-
- tion can take at least one of the following roles:
- provisioning if it delivers local event logs to
- be collaboratively mined; **mining** if it applies

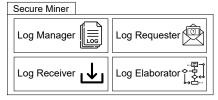

Figure 3: Sub-components of the Secure Miner

process mining algorithms using event logs retrieved from provisioners. In Fig. 2,

we propose the high-level schematization of the CONFINE framework. In our solution, every organization hosts one or more nodes hosting components (the 172 names of which will henceforth be formatted with a teletype font). Depending 173 on the played role, nodes come endowed with a Provisioner or a Secure Miner component, or both. The Provisioner component consists of the following two main sub-components. The Log Recorder registers the events taking place in the 176 organizations' systems. The Log Provider delivers on-demand data to mining 177 players. The hospital and all other parties in our example record Alice and Bob's 178 cases using the Log Recorder. The Log Recorder is queried by the Log Provider for event logs to be made available for mining. The latter controls access to local 180 event logs by authenticating data requests by miners and rejecting those that come 181 from unauthorized parties. In our motivating scenario, the specialized clinic, the 182 pharmaceutical company, and the hospital leverage Log Providers to authenticate the miner party before sending their logs. The Secure Miner component shelters 184 external event logs inside a protected environment to preserve data confidentiality 185 and integrity. Notice that Log Providers accept requests issued solely by Secure Miners. Next, we provide an in-depth focus on the latter.

The Secure Miner. The primary objective of the Secure Miner is to allow miners to securely execute process mining algorithms using event logs retrieved from provisioners such as the specialized clinic, pharmaceutical company, and the hospital in our example. Secure Miners are isolated components that guarantee data inalterability and confidentiality. In Fig. 3, we show a schematization of the Secure Miner, which consists of four sub-components: (i) Log Requester; (ii) Log Receiver; (iii) Log Manager; (iv) Log Elaborator. The Log Requester and the Log Receiver are the sub-components that we employ during the event log

retrieval. Log Requesters send authenticable data requests to the Log Providers. The Log Receiver collects event logs sent by Log Providers and entrusts them 197 to the Log Manager, securing them from accesses that are external to the Secure Miner. Miners of our motivating scenario, such as the university and the national institute of statistics, employ these three components to retrieve and store Alice and Bob's data. The Log Elaborator merges the event data locked in the Secure 201 Miner to have a global view of the inter-organizational process comprehensive of 202 activities executed by each involved party. Thereupon, it executes process mining 203 algorithms in a protected environment, inaccessible from the outside computation environment. In our motivating scenario, the Log Elaborator combines the traces 205 associated with the cases of Alice (i.e., T_{312}^H , T_{312}^S , and T_{312}^C) and Bob (i.e, T_{711}^H , T_{711}^S , 206 and T_{711}^{C}), generates the chronologically sorted traces T_{312} and T_{711} , and feeds them 207 into the mining algorithms (see the bottom-right quadrant of Table 1).

209 6. Realization

In this section, we outline the technical aspects concerning the realization of our solution. Therefore, we first present the enabler technologies through which we instantiate the design principles presented in Sect. 5. After that, we discuss the CONFINE interaction protocol. Finally, we show the implementation details.

214 6.1. Deployment

215

216

217

218

Figure 4 depicts a UML deployment diagram [15] to illustrate the employed technologies and computation environments. We recall that the Miner and Provisioner nodes are drawn as separated, although organizations can host both. In our motivating scenario, e.g., the hospital can be equipped with machines aimed for both mining and provisioning.

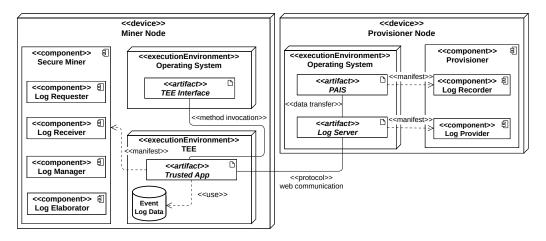

Figure 4: UML deployment diagram of the CONFINE architecture

Provisioner Nodes host the Provisioner's components, encompassing the Log Recorder and the Log Provider. The Process-Aware Information System (PAIS) manifests the Log Recorder [16]. The PAIS grants access to the Log Server, enabling it to retrieve event log data. The Log Server, on the other hand, embodies the functionalities of the Log Provider, implementing web services aimed at handling remote data requests and providing event log data to miners.

The Miner Node is characterized by two distinct execution environments: the Operating System (OS) and the Trusted Execution Environment (TEE) [5]. TEEs establish isolated contexts separate from the OS, safeguarding code and data through hardware-based encryption mechanisms. This technology relies on dedicated sections of a CPU capable of handling encrypted data within a reserved section of the main memory [17]. By enforcing memory access restrictions, TEEs aim to prevent one application from reading or altering the memory space of another, thus enhancing the overall security of the system. This dedicated areas in memory are, however, limited. Once the limits are exceeded, TEEs have to scout around in outer memory areas, thus conceding the opportunity to malicious reader to understand

the saved data based on the memory reads and writes. To avoid this risk, TEE implementations often raise errors that halt the program execution when the memory 237 demand goes beyond the available space. Therefore, the design of secure systems 238 that resort to TEEs must take into account that memory consumption must be kept under control. We leverage the security guarantees provided by TEEs [18] to protect a Trusted App responsible for fulfilling the functions of the Secure Miner and 241 its associated sub-components. The TEE ensures the integrity of the Trusted App 242 code, protecting it against potential malicious manipulations and unauthorized access by programs running within the Operating System. Additionally, we utilize the isolated environment of TEEs to securely store event log data (e.g., Alice and 245 Bob's cases). The TEE retains a private key in the externally inaccessible section of 246 memory, paired with a public key in a Rivest-Shamir-Adleman (RSA) [19] scheme 247 for attestation (only the owner of the private key can sign messages that are verifiable via the public key) and secure message encryption (only the owner of the private key can decode messages that are encrypted with the corresponding public key). In our 250 solution, access to data located in the TEE is restricted solely to the Trusted App. 251 Users interact with the Trusted App through the Trusted App Interface, which 252 serves as the exclusive communication channel. The Trusted App offers secure methods, invoked by the Trusted App Interface, for safely receiving information from the Operating System and outsourcing the results of computations. 255

6.2. The CONFINE protocol

257

We orchestrate the interaction of the components in CONFINE via a protocol.

Our protocol involves two main actors: a Secure Miner (henceforth, \mathcal{M}) and one to many Log Provisioners $(\mathcal{P}_1,...,\mathcal{P}_n \in \widehat{\mathcal{P}})$. Their behaviour is documented in Alg. 1 and Alg. 2

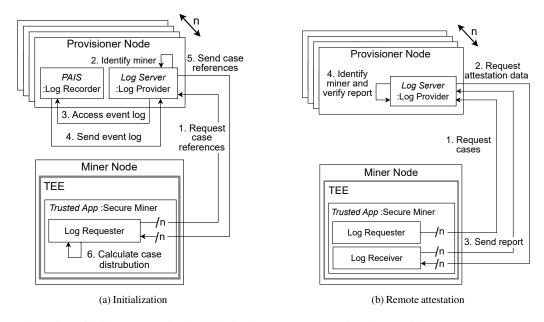

Figure 5: Unfolding example for the initialization, remote attestation phases of the CONFINE protocol

We separate it in four subsequent stages, namely (i) initialization, (ii) remote 261 attestation, (iii) data transmission, and (iv) computation. These stages are depicted 262 in Figs. 5(a), 5(b), 6(a) and 6(b), respectively. They are mainly enacted by a Miner 263 Node and n Provisioner Nodes. We assume their communication channel is 264 reliable [20] and secure [21]. In the following, we describe each phase in detail. 265 **Initialization.** The objective of the initialization stage is to inform the miner about the distribution of cases related to a business process among the Provisioner Nodes. 267 At the onset of this stage, the Log Requester within the Trusted App issues n268 requests, one per Log Server component, to retrieve the list of case references they 269 record (step 1 in Fig. 5(a)). Following sender authentication (2), each Log Server 270 retrieves the local event log from the PAIS (3, 4) and subsequently responds to the Log Requester by providing a list of its associated case references (5). After collecting 272 these n responses, the Log Requester delineates the distribution of cases. In the

context of our motivating scenario, by the conclusion of the initialization, the miner gains knowledge that the case associated with Bob, synthesized in the traces T_{711}^H and T_{711}^C , is exclusively retained by the hospital and the specialized clinic. In contrast, the traces of Alice's case, denoted as T_{312}^H , T_{312}^C , and T_{312}^S , are scattered across all three organizations.

Remote attestation. The remote attestation serves the purpose of establishing trust 279 between miners and provisioners in the context of fulfilling data requests. This phase 280 adheres to the overarching principles outlined in the RATS RFC standard [22] serving 281 as the foundation for several TEE attestation schemes (e.g., Intel EPID,² and AMD SEV-SNP³). Remote attestation has a dual objective: (i) to furnish provisioners with 283 compelling evidence that the data request for an event log originates from a Trusted 284 App running within a TEE; (ii) to confirm the specific nature of the Trusted App 285 as an authentic Secure Miner software entity. This phase is triggered when the Log Requester sends a new case request to the Log Server, specifying: (i) the 287 segment size (henceforth, seg_size), and (ii) the set of the requested case references. 288 Both parameters will be used in the subsequent data transmission phase. Each of 289 the n Log Servers commences the verification process by requesting the necessary 290 information from the Log Receiver to conduct the attestation (2). Subsequently, the Log Receiver generates the attestation report containing the so-called measurement of the Trusted App, which is defined as the hash value of the combination of its source code and data. Once this report is signed using the attestation private key associated with the TEE's hardware of the Miner Node, it is transmitted by the Log

³amd.com/en/processors/amd-secure-encrypted-virtualization. Accessed: 15/01/2024.

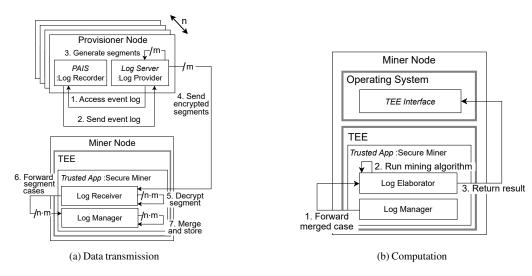

Figure 6: Unfolding example for the data transmission and computation phases of the CONFINE protocol

Receiver to the Log Servers alongside the attestation public key of the Miner Node (3). The Log Servers authenticate the miner using the public key and decrypt 297 the report (4). In this last step, the Log Servers undertake a comparison procedure in which they juxtapose the measurement found within the decrypted report against 290 a predefined reference value associated with the source code of the Secure Miner. 300 If the decrypted measurement matches the predefined value, the Miner Node gains 301 trust from the provisioner. 302 Data transmission. Once the trusted nature of the Trusted App is verified, the Log Servers proceed with the transmission of their cases. To accomplish this, each Log 304 Server retrieves the event log from the PAIS (steps 1 and 2, in Fig. 6(a)), and filters 305 it according to the case reference set specified by the miner. Given the constrained 306 workload capacity of the TEE, it is imperative for Log Servers to partition the filtered event log into distinct segments. Consequently, each Log Server generates $m \log$ segments comprising a variable count of entire cases (3). The cumulative size of

these segments is governed by the threshold parameter specified by the miner in the initial request (step 1 of the remote attestation phase, Fig. 5(b)). As an illustrative 311 example from our motivating scenario, the Log Server of the hospital may structure the segmentation such that T_{312}^{H} and T_{711}^{H} reside within the same segment, whereas 313 the specialized clinic might have ${\cal T}_{312}^S$ and ${\cal T}_{711}^S$ in separate segments. Subsequently, 314 the n Log Servers transmit their m encrypted segments to the Log Receiver of 315 the Trusted App (4). The Log Receiver, in turn, collects the $n \times m$ responses in a 316 queue, processing them one at a time. After decrypting the processed segment (5), 317 the Log Receiver forwards the cases contained in the segment to the Log Manager (6). To reconstruct the process instance, cases belonging to the same process instance 319 must be merged by the Log Manager resulting in a single trace (e.g., T_{312} for Alice 320 case) comprehensive of all the events in the partial traces (e.g., T_{312}^H, T_{312}^S and T_{312}^C 321 for Alice case). During this operation, the Log Manager applies a specific merging schema (i.e., a rule specifying the attributes that link two cases during the merge) 323 as stated in [12]. In our illustrative scenario, the merging schema to combine the 324 cases of Alice is contingent upon the linkage established through their case identifier (i.e., 312). We underline that our proposed solution facilitates the incorporation of diverse merging schemas encompassing distinct trace attributes. The outcomes arising from merging the cases within the processed segment are securely stored by the Log Manager in the TEE. 329 **Computation.** The Trusted App requires all the provisioners to have delivered cases referring to the same process instances. For example, when the hospital and the other organizations have all delivered their information concerning case 312 to the Trusted App, the process instance associated with Alice becomes eligible for computation. Upon meeting this condition, the Log Manager forwards the case earmarked for

Algorithm 1: Secure Miner's behavior in CONFINE.

```
Input: \hat{P} = \{P_1, ..., P_n\}, the (references to) n log provisioners;
                             seg_size, the maximum size of the log segment to be transmitted by the log provisioners.
           \textbf{Data: } \textit{CIDMap}: \widehat{\text{CID}} \rightarrow 2^{\widehat{\mathcal{P}}} \text{, a map from case references } \textit{cid} \in \widehat{\text{CID}} \text{ to the set of log provisioners in } \widehat{\mathcal{P}} \text{ ;}
                           PMap: \hat{\mathcal{P}} \rightarrow 2^{\widehat{\text{CID}}}, a map from log provisioners \mathcal{P} \in \hat{\mathcal{P}} to the set of references to their cases in \widehat{\text{CID}};
                           Cases : \widehat{CID} \to \widehat{C}, a map from case references cid \in \widehat{CID} to a set of cases in \widehat{C}.

                                                                                                                                                                                                   // When all the pieces of some cid have arrived to \mathcal{M}'s Log Manager
                   dom(CIDMap) \leftarrow dom(CIDMap) \setminus \{cid\}
                                                                                                                                                                                             // Remove cid from the domain of cases which still needs to be processed
18
                 yield Cases[cid] to \mathcal{M}.LogElaborator
                                                                                                                                 // Forward the case \mathit{cid} to the Log Elaborator of \mathcal M for mining – \mathit{computation} phase in Fig. 6(b)
```

computation to the Log Elaborator (step 1 in Fig. 6(b)). Subsequently, the Log 335 Elaborator proceeds to input the merged case into the process mining algorithm (2). Ultimately, the outcome of the computation is relayed by the Log Elaborator 337 from the TEE to the TEE Interface running atop the Operating System of the 338 Miner Node (3). The CONFINE protocol does not impose restrictions on the 339 post-computational handling of results. In our motivating scenario, the University 340 and the National Institute of Statistics, serving as miners, disseminate the outcomes of 341 computations, generating analyses that benefit the provisioners (though the original 342 data are never revealed in clear). Furthermore, our protocol enables the potential for provisioners to have their proprietary Secure Miner, allowing them autonomous control over the computed results.

Algorithm 2: Provisioner's behavior in CONFINE.

```
Input: \widehat{\mathcal{M}} = \{\mathcal{M}_1, ..., \mathcal{M}_s\}, the (references to) s miners.
Implements: Provisioner, instance P
Uses: AuthenticatedPerfectPointToPointLink, instance al.

6.3. Implementation

We implemented the Secure Miner component as an Intel SGX⁴ trusted application, encoded in Go through the EGo framework.⁵ We resort to a TLS [23] communication channel between miners and provisioners over the HTTP web protocol to secure the information exchange. To demonstrate the effectiveness of our framework, we re-implemented and integrated the *HeuristicsMiner* discovery algorithm [24] within the Trusted Application. Our implementation of CONFINE, including the *HeuristicsMiner* in Go, is openly accessible at the following URL:

⁴sgx101.gitbook.io/sgx101/. Accessed: 15/01/2024.

⁵docs.edgeless.systems/ego. Accessed: 15/01/2024.

7. Evaluation

366

367

369

370

In this section, we evaluate our approach through the testing of our tool implementation. We begin with a convergence analysis to demonstrate the correctness of the collaborative data exchange process. Subsequently, we gauge the memory usage with synthetic and real-life event logs, to observe the trend during the enactment of our protocol and assess scalability. We recall that we focus on memory utilization since the availability of space in the dedicated areas is limited as we discussed in Sect. 6.1. We discuss our experimental results in the following. For the sake of reproducibility, we make available all the testbeds and results in our public code repository (linked above).

Output convergence. To experimentally validate the correctness of our approach

Output convergence. To experimentally validate the correctness of our approach in the transmission and computation phases (see Sect. 6), we run a *convergence* test. To this end, we created a synthetic event log consisting of 1000 cases of 14 events on average (see Table 2) by simulating the inter-organizational process of our motivating scenario (see Fig. 1)⁶ and we partitioned it in three sub-logs (one per involved organization), an excerpt of which is listed in Table 1. We run the stand-alone *HeuristicsMiner* on the former, and processed the latter through our

⁶We generated the event log through BIMP (https://bimp.cs.ut.ee/). We filtered the generated log by keeping the sole events that report on the completion of activities, and removing the start and end events of the pharmaceutical company and specialized clinic's sub-processes.

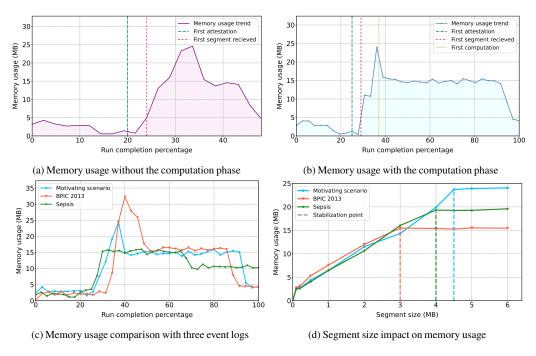

Figure 8: Memory usage test results

CONFINE toolchain. As expected, the results converge and are depicted in Fig. 7 in the form of a workflow net [27]. For clarity, we have colored activities recorded by 373 the organizations following the scheme of Table 2 (black for the hospital, blue for the 374 pharmaceutical company, and green for the specialized clinic). 375 Memory usage. Figures 8(a) and 8(b) display plots corresponding to the 376 runtime memory utilization of our CONFINE implementation (in MegaBytes). 377 Differently from Fig. 8(b), Fig. 8(a) excludes the computation stage by leaving the 378 HeuristicsMiner inactive so as to isolate the execution from the mining-specific operations. The dashed lines mark the starting points for the remote attestation, the 380 data transmission and the computation stages. We held the seg size constant at 2000 381 KiloBytes. We observe that the data transmission stage reaches the highest peak of 382 memory utilization, which is then partially freed by the subsequent computation

stage, steadily occupying memory space at a lower level. To verify whether this phenomenon is due to the synthetic nature of our simulation-based event log, we also 385 gauge the runtime memory usage of two public real-world event logs too (Sepsis [25] 386 and BPIC 2013 [26]). The characteristics of the event logs are summarized in Table 2. Since those are intra-organizational event logs, we split the contents to mimic an inter-organizational context. In particular, we separated the Sepsis event log based 389 on the distinction between normal-care and intensive-care paths, as if they were 390 conducted by two distinct organizations. Similarly, we processed the BPIC 2013 391 event log to sort it out into the three departments of the Volvo IT incident management system. Figure 8(c) depicts the results. We observe that the processing of the BPIC 393 2013 event log demands more memory, particularly during the initial stages, probably 394 owing to its larger size. Conversely, the Sepsis event log turns out to entail the least 395 expensive run. To verify whether these trends are affected by the dimension of the exchanged data segments, we conducted an additional test to examine the trend of 397 memory usage as the *seg_size* varies with all the aforementioned event logs. Notably, 398 the polylines displayed in Fig. 8(d) indicate a linear increment of memory occupation 390 until a breakpoint is reached. After that, the memory in use is steady. These points, 400 marked by vertical dashed lines, correspond to the seg_size value that allows the provider's segments to be contained in a single data segment. Scalability. In this subsection, we examine the scalability of the Secure Miner, 403 focusing on its capacity to efficiently manage an increasing workload in the presence of limited memory resources. We implemented three distinct test configurations 405 gauging runtime memory usage as variations of our motivating scenario log. In particular, we considered (I) the maximum number of events per case, (II) the number of cases $|\widehat{\text{CID}}|$, and (III) the number of provisioning organizations $|\widehat{\mathcal{O}}|$

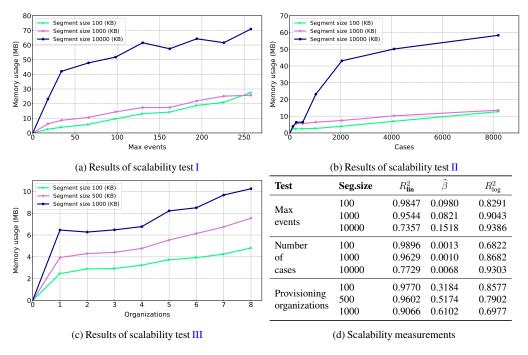

Figure 9: Scalability test results

as independent integer variables. To conduct the test on the maximum number of events, we added a loop back from the final to the initial activity of the process model, progressively increasing the number of iterations $2 \le x_0 \le 16$ at a step of 2, 411 resulting in $18+16 \cdot (x_{05}-1)$ events. Concerning the test on the number of cases, we simulated additional process instances so that $|\widehat{\text{CID}}| = 2^{x_{cid}}$ having $x_{cid} \in \{7, 8, ..., 13\}$. Finally, for the assessment of the number of organizations, the test necessitated the 414 distribution of the process model activities' into a variable number of pools, each 415 representing a different organization ($|\hat{\mathcal{O}}| \in \{1,2,...,8\}$). We parameterized the above 416 configurations with three segment sizes (in KiloBytes): $seg_size \in \{100,1000,10000\}$ for tests I and II, and $seg_size \in \{100,500,1000\}$ for test III (the range is reduced without loss of generality to compensate the partitioning of activities into multiple 419 organizations). To facilitate a more rigorous interpretation of the output trends across

varying seg_size configurations, we employ two well-known statistical measures. As a primary measure of goodness-of-fit, we employ the coefficient of determination R^2 [28], which assesses the degree to which the observed data adheres to the linear $(R^2_{\rm lin})$ and logarithmic $(R^2_{\rm log})$ regressions derived from curve fitting approximations. To further delve into the analysis of trends with a high $R^2_{\rm lin}$, we consider the slope $\hat{\beta}$ of the approximated linear regression [29].

Table 9(d) lists the measurements we obtained. We describe them to elucidate the 427 observed patterns. Figure 9(a) depicts the results of test I, focusing on the increase of memory utilization when the number of events in the event logs grows. We observe that the memory usage for seg_size 100 and 1000 (depicted by green and lilac lines, 430 respectively) are quite similar, whereas the setting with seg_size 10,000 (blue line) 431 exhibits significantly higher memory usage. For the settings with seg_size 100 and 432 $1000,\,R_{\mathrm{lin}}^2$ approaches 1, signifying an almost perfect approximation of the linear relation, against lower R^2_{\log} values. In these test settings, $\hat{\beta}$ is very low yet higher than 0, thus indicating that memory usage is likely to continue increasing as the number of max events grows. The configuration with $seg_size~10,000$ yields a higher R_{log}^2 value, thus suggesting a logarithmic trend, hence a greater likelihood of stabilizing memory usage growth rate as the number of maximum events increases. In Fig. 9(b), we present the results of test II, assessing the impact of the number of cases on the memory consumption. As expected, the configurations with seg_size set to 100 and 1000 exhibit a trend of lower memory usage than settings with seg_size $10,\!000$. The $R_{\rm lin}^2$ score of the trends with $seg_size~100$ and 1000 indicate a strong linear relationship between the dependent and independent variables compared to the trend with seg_size 10,000, which is better described by a logarithmic regression $(R_{\rm log}^2=0.9303).$ For the latter, the $R_{\rm log}^2$ value is higher than the corresponding $R_{\rm lin}^2$

thus suggesting that the logarithmic approximation is better suited to describe the trend. Differently from test I, the $\hat{\beta}$ score associated with the linear approximations of the trends with seg_size 100 and 1000 approaches 0, indicating that the growth rate of memory usage as the number of cases increases is negligible. In Fig. 9(c), we present the results of test III, on the relation between the number of organizations and the memory usage. The chart shows that memory usage trends increase as 451 provisioning organizations increase for all three segment sizes. The $R_{\rm lin}^2$ values 452 for the three *seg_sizes* are very high, indicating a strong positive linear correlation. The test with seg_size 100 exhibits the slowest growth rate, as corroborated by the lowest $\hat{\beta}$ result (0.3184). For the configuration with seg_size 500, the memory usage increases slightly faster ($\hat{\beta} = 0.5174$). With seg_size 1000, the overall memory usage 456 increases significantly faster than the previous configurations ($\hat{\beta} = 0.6102$). We 457 derive from these findings that the Secure Miner may encounter scalability issues when handling settings with a large number of provisioning organizations. Further investigation is warranted to determine the precise cause of this behavior and identify potential mitigation strategies. 461

In the next section, we conclude our work and outline future research directions
based upon our current findings and the limitations of our approach.

8. Conclusion and Future Work

Confidentiality is paramount in inter-organizational process mining due to the transmission of sensitive data across organizational boundaries. Our research investigates a decentralized secrecy-preserving approach that enables organizations to employ process mining techniques with event logs from multiple organizations while ensuring the protection of privacy and confidentiality. Our solution offers

a number of directions to walk along for improvement. We operate under the assumption of fair conduct by data provisioners and do not account for the presence 471 of injected or maliciously manipulated event logs. In addition, we assume that miners and provisioners exchange messages in reliable communication channels where no loss or bit corruption occurs. Our approach relies on certain assumptions about event log data, including the existence of a universal clock for event timestamps, which may 475 not be realistic in situations where organizations are not perfectly synchronized. We 476 aim at enhancing our approach to make it robust to the relaxation of these constraints. 477 Our future work encompasses the integration of usage control policies that specify rules on event logs' utilization. We plan to design policy enforcement and monitoring 479 mechanisms to achieve this goal following the principles already addressed in [30, 31]. 480 Our solution embraces process mining techniques in a general way. However, we 481 believe the presented approach is compatible with declarative model representations [32]. Therefore, trusted applications could compute and store the entire set of 483 rules representing a business process, and users may interact with them via trusted 484 queries. Finally, in our implementation, we have focused on process discovery tasks. 485 Nevertheless, our approach has the potential to seamlessly cover a wider array of process mining functionalities such as conformance checking, and performance analysis techniques. Implementing them and showing their integrability with our approach paves the path for future research endeavors. 489 **Acknowledgments.** The authors thank Giuseppe Ateniese for the fruitful discussion 490 and insights. This research work was partly funded by MUR under PRIN grant B87G22000450001 (PINPOINT), by the Latium Region under PO FSE+ grant B83C22004050009 (PPMPP), and by the EU-NGEU under the NRRP MUR grant PE00000014 (SERICS).

EXTENSION PLAN:

Extended introduction

Add Background Section

Add more related work

Modify the motivating scenario (and the design alongside the implementation) with more attributes involved in the event event log (for example, the famous ID that might not be shared among providers, many of those having differing attributes and codes to refer to an instance.

Add Notation and formalization of event logs, merging, partitioning and segmentation

Add Soundness and completeness theorems

Add threat model

Full pseudocode of the protocol ∨

More real-world event logs (plus two, at least) with associated tests

Add communication overhead v. segment size charts: elab time vs segment size; total time (incl. network) vs segment size.

Integrate declarative conformance checking (let it be with Janus or MINERful).
